INTRODUCTION

The goal of this application note is to present a technique for managing several external I/O interrupts with a member of the ST7 series of MCUs (here a ST72251).

1 I/O CELL STRUCTURE

Each pin of the microcontroller I/O port can be programmed independently as digital input (with or without interrupt generation) or digital output. Some have also alternate function (SPI, SCI, Timers...). If you want to change the I/O port configuration, take care to respect the state transition diagram (please, refer to the datasheet for more details).

Figure 1. I/O Block Diagram
2 INTERRUPT GENERATION

When you use several pins as interrupt pull up inputs, problems may occur if more than one input generates an interrupt within the same period of time. Some will be “masked”, and then won’t be taken into account.

All pins configured as external interrupt mode are connected together in a logical “NAND” function to the same core interrupt vector (see figure 1). An external interrupt is an edge and/or a low level applied on a pin configured as an input with pull up and interrupt.

To get a high level at the interrupt line, all interrupt pins must be high.

The sensitivity chosen for interrupts in our application is falling edge (please, refer to the miscellaneous register).

Let’s take a look on the possible problem:

As we can see, some interrupts may be inhibited by others if the software doesn’t prevent such events. It’s because of the logical NAND performed in the chip that the interrupt vector won’t be able to treat a nested interrupt.

This application note presents then a solution in order to detect and to treat all falling edges of potential interrupt pins.

3 DETECTING INTERRUPTS

The interrupt’s edge or level sensitivity has to be programmed by software using the miscellaneous register. In this application note, we then chose “falling edge”.

We use the Port C (PC0 to PC4) as input with pull-up and interrupt (external interrupt 1). To configure it correctly, please refer to the datasheet. We use PA0 as output to apply on Port C pins a low level to create an interrupt.
The main point of the technique used here consists on enabling and disabling inputs which are potential sources of interrupt. Once an interrupt is detected (its falling edge), it’s automatically treated (the main program goes to the interrupt subroutine) and then disabled. If another interrupt occurs, all pins are tested (if the OR register bit is set, the interrupt is enabled) in order to see a falling edge which hasn’t been treated yet. Once a high level is detected (by polling) on a pin which previously generated an interrupt, the interrupt mode is enabled once again (setting OR bit).

You can have a different interrupt subroutine depending on the pin responsible of the interrupt.

When using this technique, the user is able to detect every single falling edge interrupt with no risk of overlapping between them.

The interrupt subroutine must test every pin and make the right relative jump to the interrupt procedure according to the pin which generated the interrupt.
Figure 1. Polling subroutine

```
Begin

Polling on pin 0
Pin 0=1

OR 0=1?
Yes

Polling on pin n
Pin n=1

OR n=1?
Yes

user's program

No

Set OR 0

No

Set OR n
```

n is the number of pins able to generate an interrupt.
n still represents the number of pins able to generate an interrupt.

In the main program, port C pins are tested to be enabled and the LED corresponding to the last pin which caused the interrupt toggles until another interrupt occurs.
5 SOFTWARE

The assembly code given below is guidance only. The complete software with all the files can be found in the software library.

```
